Objective: To address the following questions: (1) What evidence (ie, psychometric data collected in pediatric primary care, patient outcome data) exists for the various methods used to identify adolescent depression in primary care? and (2) What identification practices are currently in use?

Data Sources: We systematically searched MEDLINE for English-language articles using specific search terms and examined relevant titles, abstracts, and articles.

Study Selection: We reviewed 1743 MEDLINE abstracts. Seventy-four articles were pulled for examination, with 30 articles meeting full criteria.

Data Extraction: Five studies had adequate psychometric data on various adolescent depression identification methods in primary care. Only 1 compared the diagnostic accuracy of physicians trained to ask depression questions vs physicians trained in the use of a diagnostic aid. Six studies reported on current practice. Evidence regarding sensitivity, specificity, positive predictive value, and negative predictive value was sought for question 1. Frequency of screening was sought for question 2.

Data Synthesis: Review of these articles found that few health care professionals use systematic depression identification methods, despite some growing evidence for their validity, feasibility, and possible efficacy.

Conclusion: Available evidence indicates that primary care professionals would improve their rates of depression diagnosis through training, but even more so by using adolescent symptom rating scales.

Arch Pediatr Adolesc Med. 2006;160:694-704

STUDIES HAVE FOUND THAT 3% to 9% of teenagers meet criteria for depression at any one time, and at the end of adolescence, as many as 20% of teenagers report a lifetime prevalence of depression.1-4 Adolescent depression may affect the teen’s socialization, family relations, and performance at school, often with potentially serious long-term consequences.5 Adolescents with depression are at risk for increased hospitalizations, recurrent depressions, psychosocial impairment, alcohol abuse, and antisocial behaviors as they grow up.6,8 Of course, the most devastating outcome of concern for adolescent depression is suicide, the third leading cause of death among older adolescents.9

Despite the severe morbidity and mortality associated with adolescent depression, most studies report that only 1 in 4 to 1 in 3 adolescents with depression are receiving treatment for this disorder.10,11 Extant data suggest that depression is relatively common in pediatric settings12,13 and is often unidentified by pediatric professionals.14,15 Pediatricians, however, do feel responsible for identifying adolescent depression16 and most of the major professional organizations have acknowledged the importance of identifying depression and suicidal behavior in youth.17-19 To improve the identification and treatment of adolescent depression, primary care health professionals may need to adapt the service delivery models currently used in treating adults with depression. While depression screening and management are now considered to be an essential function of the primary care setting for adults,20-22 no definitive recommendations have been made in support of adolescent depression screening in primary care.

For editorial comment see page 755

In light of the significant morbidity and mortality of adolescent depression; its high prevalence in pediatric primary care; the existence of promising treatments such as cognitive behavioral therapy,23 interpersonal therapy for adolescents,24 and medication25 (despite the current “black box” warning26); and its underrecognition by pediatricians despite their good intentions, it is surprising that no literature, to our knowledge, has systematically reviewed the available evidence regarding the various methods available and in use for the identification of adolescent depression in pediatric primary care. We conducted a literature search to determine (1) What evidence exists for the various methods

Author Affiliations: Division of Child and Adolescent Psychiatry, Department of Psychiatry, Columbia University and Center for the Advancement of Children’s Mental Health, Columbia University/New York State Psychiatric Institute, New York.
used to identify adolescent depression in primary care? and (2) What identification practices are currently in use? Question 1 includes the following: (1) the availability of psychometric data assessing adolescent depression screening and identification methods in pediatric primary care and (2) available evidence regarding the feasibility, acceptability, cost, and benefit to patients of available identification methods.

This search focused on psychometric data comparing the use of general psychosocial screening tools (eg, Child Behavior Checklist), depression-specific tools (eg, self-reports, health care professional–rated checklists), reliance on chief complaints, and the use of parent and/or adolescent interview techniques to identify adolescent depression in primary care. Psychometric data sought included sensitivity (the proportion of those with the disease or condition, as measured by the gold standard, who have positive results by the test being studied), specificity (the proportion of those without the disease or condition, as measured by the gold standard, who have negative results by the method, criteria, or test being studied), positive predictive value (PPV), and negative predictive value (NPV) of different identification methods. While the gold standard depression diagnosis typically would involve experienced mental health professionals using high-quality assessment techniques and gathering information from multiple informants, the gold standard diagnosis may be a structured interview or other such approximation. We sought studies that clearly defined their gold standard in primary care. In addition, any available evidence regarding the feasibility, acceptability, cost, and outcome for the adolescent patient of any of the various identification methods was sought. Lastly, by identifying methods currently used in pediatric primary care settings, we hoped to find explanations for the current underrecognition.

We searched MEDLINE (English-language articles only) for all years up through December 28, 2004, using the following key words: primary care or pediatric$ ($ indicates a wild-card term) or family med$ or GP or health clinic or health center or teen clinic or teen center or adolescent clinic or adolescent center or family physician$ or family pract$ or adolescent medicine or ambulatory care and depress$ or mood$ and adolescent$ or teen$. Articles targeting populations with specific somatic symptoms, physical illnesses, or other risk factors; studies not focusing on adolescents; or those discussing children generally but not separating out older children (older than 10 years) were eliminated. Articles that dealt with general psychosocial issues, psychological distress, or suicidality, rather than depression, were included only if depression or mood disorders were also mentioned in the abstract and then specifically examined in the study as well. Population surveys and service use assessments were discarded because they did not take place in primary care, as were treatment articles that did not describe the mechanism of identification. Lastly, English-language articles that described screening conducted in non–English-speaking countries were discarded. In addition, a hand search of the references from the relevant articles found in the search was also conducted.

We identified and hand reviewed 1743 titles (most with abstracts). Seventy-four full articles were selected for initial review based on relevance. Twenty-nine articles met criteria for final review: 24 addressed the first question regarding identification methods in primary care (Table 1) and 6 (including 1 from Table 1) focused on health care professional–reported current practices (Table 2). Final results from a previously published study were published in January 2005 and that article is included as the 25th article in Table 1.

IDENTIFICATION DATA IN PRIMARY CARE (QUESTION 1 PART 1)

Of the 25 articles presented in Table 1, only 5 present data on the sensitivity, specificity, PPV, and NPV of a designated identification method in primary care. In the first of the 5 studies, Winter et al trained pediatricians to administer the mood module of the Primary Care Evaluation of Mood Disorders to 100 consecutive adolescents. Using the Primary Care Evaluation of Mood Disorders interview as the gold standard to validate a self-report (Beck Depression Inventory for Primary Care), analyses demonstrated a sensitivity and specificity of 91% at a cutoff score of 4 or higher. With their sample prevalence of 11% for major depressive disorder, the PPV for the Beck Depression Inventory for Primary Care was 55.6% and the NPV, 98.7%.

In the second study, Johnson et al attempted to validate the Patient Health Questionnaire for Adolescents, which assesses depression, eating disorders, and substance use. Using a mental health professional–administered telephone interview based mostly on the Primary Care Evaluation of Mood Disorders mood module as the gold standard diagnosis, the Patient Health Questionnaire for Adolescents yielded a sensitivity of 73%, specificity of 94%, and PPV of 56% for major depressive disorder, which rose to 62% for “any depressive disorder” (n=403).

In the third study, Schubiner and colleagues examined the accuracy of physician diagnosis aided by a self-report questionnaire, as well as the accuracy of physician diagnosis based on a mnemonic verbal interview, comparing both with a gold standard, semistructured, psychologist-administered interview. Physicians at an urban adolescent clinic were randomized into 2 groups, 1 trained to use the Safe Times Questionnaire (a 7-subscale screen with 1 subscale for depression/suicide comprising 5-7 items) vs 1 trained to conduct interviews based on the Safe Times Questionnaire mnemonic verbal interview. This latter group was not as accurate in depression identification as the Safe Times Questionnaire screening tool group, with area under the receiver operating characteristic curves of 88% for the screen vs 50% for the interview (P<.05), sensitivity of 80% vs 18% (P<.05), specificity of 91% vs 93%, PPV of 71% vs 43%, and NPV of 95% vs 80% (P<.05), In this study, depression prevalence was 21%.

In the fourth study, Yates et al administered the Mood and Feelings Questionnaire to 267 adolescent primary care attendees in Great Britain, with the urban subgroup (n=130) also receiving the Schedule for Affective Disorders and Schizophrenia for School-Age Children diagnostic interview. Full details of this study are described elsewhere. Based on receiver operating characteristic curve analyses from an earlier study, investigators chose a cutoff score of 17, rather than the accepted 26 in clinical samples, to

provide optimal sensitivity and specificity in their adolescent population with an estimated depression prevalence of 20%. Total and internalizing parent Child Behavior Checklist27 scores were modestly correlated with adolescent-rated mood symptoms (Spearman ρ=0.203 and 0.239; P<.002 and <.001, respectively).36 Recalculation of the data
by Yates and colleagues, which is presented in Table 1 in a different article (by Gledhill et al39), indicates that the Mood and Feelings Questionnaire yielded a PPV of 38% (n=82).

The fifth and final study39 is a follow-up to the Yates et al study40 and relied on Mood and Feelings Questionnaire cutoff scores of 17 for first-stage screening. Gledhill et al39 trained 10 London general practitioners (GPs) in identification and management of adolescent depression and use of an unspecified, structured Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition65 (DSM-IV)–based depression questionnaire while interviewing the adolescent. Blinded-GP diagnosis was compared with gold standard diagnosis made by positive first-stage Mood and Feelings Questionnaire screens and follow-up Schedule for Affective Disorders and Schizophrenia for School-Age Children42 interviews. Of 184 adolescents seen, physicians improved pretraining sensitivity and PPV (20% and 33%) to 43% and 75% posttraining, respectively. While improved, GPs still failed to identify more than half of adolescents with depression.

While, to our knowledge, these 5 articles represent the best psychometric data available, 2 other studies (3 articles) from Table 1 used a 2-stage screening method to provide some data on PPVs but not sensitivity or specificity. One of these studies is the Youth Partners in Care study,23,34 in which Asarnow et al preliminarily report a PPV lower than 50% for any depressive disorder using the Center for Epidemiological Studies Depression Scale34 (CES-D) and questions from the Composite International Diagnostic Interview.31 In the second study, Logan and King58 administered the Reynolds Adolescent Depression Scale59 in a general pediatric clinic and obtained data suggesting PPVs of 73.3% to 88% for “any DSM-IV depressive disorder.” Among youth identified as having depression based on the second-stage youth report, 79% of parents failed to endorse a single depression symptom.

In addition, another 6 studies provide some limited data about identification methods in primary care. Pfaff et al66 trained primary care professionals to identify youths at risk for suicide and found that physicians’ ability to recognize high scorers on the CES-D (score ≥16) increased from 45.1% to 62.9% after training. No definitive diagnostic assessment was used, limiting firm conclusions about training. Another study, by Adams et al,28 validated a health care professional–rated, general, psychosocial, adolescent risk screen that included 1 depression question, The Perkins Adolescent Risk Screen (PARS). Medical personnel were trained to use the PARS, while adolescents completed the Children's Depression Inventory65 (CDI), a Periodic Adolescent Preventive Services Visit Form of the American Medical Association’s Guidelines for Adolescent Preventive Services17 (GAPS), and a PARS self-evaluation.28 The single PARS mood item correlated significantly with total CDI score (r=0.58; P<.01) and with mood items from the GAPS (r=0.48; P<.01). The self-reported PARS mood item correlated significantly (r=0.47; P<.001; n=188) with the health care professional–rated mood item. In another adolescent medicine clinic study by Smith et al,73 where positive State-Trait Anxiety Inventory79 and CDI screens (n=205) were reassessed by physicians after their initial interview, screening identified 18 additional patients who were initially missed. Study health care professionals were so impressed by their inability to associate certain medical complaints with psychological issues that they decided to adopt the CDI into routine clinical care.78 Similarly, 3 other studies50,60,71 suggest that self-reports identify more youth at risk for depression than physician interviews alone. However, because these studies did not examine actual depression diagnoses, results are not definitive and may reflect some false-positive results.

Overall, of these 25 studies, only 1 study, the Schubiner et al72 study, directly compared, through a randomized controlled study, physician diagnosis (based on self-report screening tools), physician identification (based on trained interview), and gold standard mental health interviews. Only 4 studies50,58,78,84 collected information from parents about adolescents’ mood symptoms, with only 2 of these studies50,84 reporting a comparison of the results, limiting any information about this specific identification question.

Ten* of the 25 studies explored in different ways how patients’ chief complaints could identify patients at risk for depression. All suggest that sole reliance on chief complaint misses many youth with depression. In 1 study of chief complaints in an adolescent clinic,36 while depression and suicidality were more prominent in those initially seen with either psychological complaints or a combination of medical and psychological complaints, depression symptom prevalence in the patients only with medical chief complaints was still high: 21% of those with just medical complaints scored 16 or higher on the Beck Depression Inventory.37 Similar results are described in other studies.66-68,74,78,84

**CHALLENGES IN INCORPORATION OF IDENTIFICATION METHODS INTO CLINICAL PRACTICE (QUESTION 1 PART 2)**

Although researchers screen teenagers for study purposes, this does not necessarily suggest feasibility of screening in routine primary care. Ten studies46,48,66-69,72,77,78 mention that the clinic or practice staff or receptionist administered the self-report identification tools to the adolescent patients, with an 11th study35 having practice health care professionals administer and rate adolescent risk checklists. Of these 11, only 535,49,69,72,78 had health care professionals use results of the identification tools clinically, with a sixth77 using clinic case managers to follow up on identified problems.

In 1 of these 11 studies, the Schubiner and colleagues77 study of the Safe Times Questionnaire, less health care professional time was spent with patients given the questionnaire vs the interview, despite more sensitive and equally specific diagnosis with the questionnaire. The 23-second difference (75 seconds vs 98 seconds), however, was not found to be significant. In another of the 11 studies, the Burns et al study,35 although the practice incorporated a health care professional–administered psychosocial risk screen (PARS) into routine care, a medical record review showed that only 49% of patients had a completed PARS.

**Table 2. Health Care Professional–Reported Current Adolescent Depression Identification Practice**

Abbreviations: NA, not available; SD, standard deviation.
minister the Primary Care Evaluation of Mood Disorders mood module in clinical practice, but unfortunately, no information was given about the feasibility of such endeavors in nonresearch settings. 

Two of the 11 studies incorporated adolescent general self-reports that included depression questions into practice. In , 99% of community health centers implemented the American Medical Association's GAPS into clinical practice. While a medical record review found GAPS screening forms in 76% of the medical records, this study was limited by selection of health centers most likely to succeed, receipt of university-provided technical assistance, and financial support for health center staff. This study did not examine how many adolescents with depression were found, but it demonstrated that the routine protocol significantly increased (1) adolescents' reported receipt of depression and suicide preventive services (pre-GAPS, 16% and 7%; post-GAPS, 34% and 22%, respectively; \( P < .001 \)), (2) medical record documentation of depression and suicide screening (pre-GAPS, 3% and 2%; post-GAPS, 79% and 78%, respectively; \( P < .001 \)), and (3) medical record documentation of family history of mental illness (pre-GAPS, 40%; post-GAPS, 53%, \( P < .001 \)). Sustained feasibility of this protocol was not examined.

In the second study that incorporated general self-reports, 1012 adolescents attending an inner-city adolescent clinic for routine care completed questionnaires covering several health topics. Health care professionals reviewed questionnaires that were not part of the medical record. Adolescents responded (n = 966) to questions regarding “being down or depressed,” with 127 (22%) endorsing these items “weekly” or more often. Medical record review of 124 of 127 cases found physician documentation of youths' depressive symptoms in 81% (n = 100) of medical records, demonstrating that most physicians examined the questionnaires.

**ASSESSMENT OF THE IMPACT OF IDENTIFICATION (QUESTION 1 PART 2)**

**Patient Outcomes**

Merely identifying adolescent depression may not lead to improved patient care or better mental health. Six of the 25 articles in Table 1 did examine the impact of depression identification on patient outcomes. In the Burns et al study, 35 patients identified by medical record review as having been given a PARS previously were invited back to the clinic. At follow-up, a repeat PARS, CDI, and questionnaires studying mental health interventions were administered. While only 44% of follow-up youth reported “ever receiving a mental health intervention,” 72% of those scoring “moderate” or higher on a baseline PARS and 50% of those scoring “moderate” or higher on a follow-up PARS reported receiving mental health interventions, although the study did not separate out the timing of the mental health intervention. Though this study did not make formal depression diagnoses, examine pathways to mental health intervention, and standardize the time between PARS scores, it does suggest that youth with previous positive PARS scores had higher rates of mental health intervention.

Only 1 (Asarnow et al Youth Partners in Care study) of the 6 studies attempted to implement a clinical response in primary care to self-report screens and to measure patient impact. As part of their quality improvement research initiative, evidence-based management was initiated in 1 screened arm with usual care in the other; the quality improvement group fared better, with lower CES-D scores at follow-up. Likewise, another of the 6 studies found improvement in Children's Global Assessment Scale scores in adolescents receiving GP depression interventions among GPs completing training. Yet another study used CES-D for Children scores to measure the mental health impact of inviting teenagers to general practice consultations to discuss health behavior concerns and obtain appropriate follow-up care. While the CES-D for Children was not used as a screening tool per se, those with high scores (≥16) who came for the nurse consultation visits and were independently identified as having depression by the nurses had lower CES-D for Children scores on follow-up than those with high scores who never came for visits.

Finally, in another 1 of the 6 patient outcome studies, the Schichor et al study, which incorporated general self-reports into clinical practice and did not have a comparison group, a medical record review demonstrated that of 100 adolescents with depression noted in the medical records, physicians counseled 33% (n = 33) and referred 51% (n = 51) for counseling. Follow-up showed that 55% (n = 28) of those referred completed the referral process. In total, 61% of those identified as having depression by the physicians received some form of counseling in the end, suggesting that implementing routine depression identification can yield tangible increases in care actually delivered.

**Physician Management Outcomes**

Two of the 25 studies examined physician management outcomes on some level. While 61% of the patients in the Schichor et al study received counseling, physicians actively intervened (either through counseling or referral) in 84% of the cases they identified as having depression and in 67.7% of the 124 patients with self-reported depressive symptoms. While there is no gold standard diagnosis and no comparison group in this study, these data suggest that systematic use of “trigger questions” or self-report scales can affect physician behavior.

In contrast, the Pfaff study found no changes in management strategies despite improved GP identification of suicidal risk factors and high scorers on the CES-D after GP training. However, to truly understand whether there was no impact, studies would need to follow through on patient outcomes.

**CURRENT PRACTICE (QUESTION 2)**

While the 25 articles from Table 1 provided some answers to our first question concerning the ways to identify adolescent depression in pediatric primary care, Table 2 represents the evidence for the second question concerning current practice. Six studies attempted to identify current depression identification practice by asking physicians directly either about their intentions or their reported ac-
tivities (Table 2). In 1 study, Halpern-Felsher and colleagues reported that despite physicians' feelings of responsibility for adolescent patients' suicide and depression, respectively, at preventive services visits. Likewise, in a second study, Olson and colleagues surveyed a national sample of randomly selected pediatricians (response rate, 66.2%) within a health maintenance organization, with only 15% and 17% reporting screening all (defined as at least 80%) of their adolescent patients for suicide and depression, respectively, at preventive services visits. Likewise, in a second study, Olson and colleagues surveyed a national sample of randomly selected pediatricians (response rate, 63%), finding that 46% lacked confidence that they could recognize depression, none recalling the use of any screening instrument during their last remembered case of adolescent depression and 17% using interview-based depression questions during their last remembered case of depression. Instead, identification was based mainly on chief complaints and family concerns. In a third study, Klein et al reported that prior to GAPS implementation in several practices, health care professionals reported screening 64% and 53% of their patients for depression and suicidal thoughts, but medical record documentation of such practices was found in only 3% and 2%, respectively, rendering such high self-reported rates of questionable validity.

In a fourth study, Middleman et al studied physicians' intentions to ask adolescents about high-risk behaviors. Using questionnaires, investigators presented 7 care scenarios to 64 pediatric residents, asking them to rate how likely they were to address 5 specific high-risk issues, including depression/suicide. Results indicated that residents were more likely to ask teens about sexual activity/birth control than any other high-risk behaviors. They were least likely to screen for suicide/depression and fighting/coping with anger.

Finally, 2 additional studies of pediatric professionals from 1982 and 1990, which are older and may not reflect current practice, reflect lower rates of asking patients about depression (14%) and suicide (20.8%), suggesting that despite physicians' feelings of responsibility for and good intentions to address depression and suicide, it usually does not happen.

**COMMENT**

Complicating our understanding of comparisons between studies are the different criteria used for defining depression diagnoses. While no large studies randomized both physicians and youth and compared different identification methods against a gold standard, the studies examined suggest that adolescent self-report tools using recommended clinical cutoff scores identify more patients with depression than other methods and that some adolescent depression screening tools have adequate psychometric properties and feasibility characteristics for use in primary care. However, studies also suggest that using liberal screening criteria may result in overidentification and increase the burden of false-positive results.

While several of the reviewed articles used general psychosocial distress screening tools (vs instruments with depression-specific questions), and while others that screened for general adolescent distress were not included in our search specifically focused on depression, none of these articles addressed how well these questionnaires identified depression compared with a gold standard diagnosis. Thus, the use of general distress self-report (eg, General Health Questionnaire) without depression-specific trigger questions in pediatric primary care to identify adolescent depression cannot be endorsed or repudiated herein.

Interestingly, training physicians improved their ability to identify depression through interview but not to levels as high as when self-report tools were available. While the HEADSS (home, education, activities, drug use and abuse, sexual behavior, suicidality and depression) interview assessment is often discussed in adolescent medicine, no studies of its incorporation into routine primary care for depression identification were found. Thus, we do not have any evidence that even physicians who may have adequate training are successfully using their skills in a systematic fashion. The Schubiner et al study is unique in that it studied physician diagnosis aided by a self-report tool, which approximates real-world clinical settings much more than just looking at the accuracy of cutoff scores for a screening instrument given in a vacuum with no additional clinical information. Lastly, the available evidence reviewed herein indicates that reliance on chief complaints alone is insufficient, because most patients with depression came in with medical complaints or for routine care.

**STUDIES INCORPORATING IDENTIFICATION METHODS INTO CLINICAL PRACTICE**

Studies reviewed herein that incorporated identification methods into clinical practice were limited in number and implementation design. A look at the larger literature on psychosocial issues in pediatric primary care can give some practical suggestions for facilitating clinical incorporation and information regarding cost.

A final clinical issue not yet examined is how often adolescents need to be queried about their moods and at which type of visits. A study of psychosocial screening across ages showed that screening only at well-child visits misses a significant amount of psychosocial issues. Our review also suggests that even at preventive services visits, physicians are often not screening for depression. Lastly, while self-reports may identify more teens with depression, the potential burden on practices of assessing false-positive results has not been adequately studied.

**IMPACT ON PHYSICIAN BEHAVIOR AND YOUTH OUTCOMES**

More research is needed on the assessment of impact. While 1 study did have physicians use depression self-report results to make diagnostic decisions, no single study combined all 3 necessary components: a screening component, an intervention, and an assessment of patient outcomes at follow-up. However, the Youth Partners in Care study did show that screening and triaging done by specialized staff in primary care will lead to better outcomes when proper management is put into place.

**CURRENT PRACTICE**

The studies cited herein suggest that not only is the use of adolescent depression self-reports rare but also that...
systematic physician inquiry into the moods of teenagers has been difficult to achieve. Failure to use systematic reliance screening tools or depression trigger questions may be a critical component of the problem, particularly if not coupled with increased pediatric training in this area.

More research is needed to inform pediatric professionals about valid and feasible methods to identify adolescent depression and whether such identification will yield improved patient outcomes, but our review suggests that systematic use of adolescent self-reports with depression-specific questions may be a useful diagnostic aid to pediatric professionals. While improved pediatric diagnosis alone is unlikely to significantly change patient outcomes, recognizing teenagers with depression is the first step to improved depression management. The several studies available already suggest that adding primary care interventions for adolescent depression will be useful. With prolonged suffering and suicide as a potential consequence of undiagnosed depression, pediatricians may be a critical component of the problem, and reliance screening tools or depression trigger questions has been difficult to achieve. Failure to use systematic depression alone is unlikely to significantly change patient outcomes in this area.
